Abstract

Anticipating fire behavior as climate change and fire activity accelerate is an increasingly pressing management challenge in fire-prone landscapes. In subalpine forests adapted to infrequent, stand-replacing fire, self-limitation of burn severity in short-interval fire is incompletely understood. Spatially explicit fuels data can support assessments of landscape-scale fire risk and fuel feedbacks on burn severity. For a ~1450-km² largely forested landscape in the US Northern Rocky Mountains, we used airborne lidar and imagery to predict and map canopy and surface fuels. In a fire that burned mature (>125-year-old) and also reburned young (~30-year-old) subalpine forest, we then asked: (1) How do prefire fuels and burn severity compare between young and mature forests that burned under similar fire weather conditions? (2) How well do prefire fuels and forest structure predict burn severity under extreme versus moderate fire weather? Lidar–imagery fusion predicted fuel characteristics with high accuracy across forest and shrubland vegetation. Young postfire forests had abundant, densely packed canopy fuels, and both young and mature forests had similar canopy fuel loads and coarse wood biomass. Under similar weather conditions, young and mature forests burned at similar severity. Overall, fuels were weak predictors of burn severity and, surprisingly, better predicted severity under extreme rather than moderate fire weather. Our findings are relevant for subalpine landscapes increasingly dominated by young lodgepole pine (*Pinus contorta* var. *latifolia*) forests vulnerable to short-interval fire and provide a benchmark to assess how fuels influence burn severity in future fires. Fire managers should continually reassess fuels and update expectations about fire behavior as landscapes change. Although recovering postfire forests can limit fire spread and severity for a period of time, our results suggest that young subalpine forests in the Northern Rocky Mountains have sufficient fuel loads to burn at high severity and should not be considered effective fire breaks.

INTRODUCTION

The rapid rise in fire activity across the western United States (Higuera & Abatzoglou, 2021; Westerling, 2016) is challenging the ability of land managers to anticipate fire behavior and effectively allocate limited resources for fire suppression or fuels treatment (BAH, 2015; WFEC, 2014). When possible, fire managers also identify opportunities for allowing fires or portions of fires to burn or for using prescribed fire to achieve resource benefits such as restoring historical vegetation structures and reducing fuel loads (Meyer et al., 2015; WFEC, 2014). These choices must be made in an increasingly difficult decision-making environment characterized by lengthening fire seasons (Westerling, 2016), more extreme fire weather (Abatzoglou & Williams, 2016), larger and more severe fires (Cansler & McKenzie, 2014), expanding wildland urban interface communities (Radeloff et al., 2018), widespread human ignitions (Balch et al., 2017), and legacies of fire exclusion leading to fuel accumulation in some forest types (Stephens et al., 2013). US governmental agencies use spatial assessments of fire progression and risk to manage long-duration fires (Calkin et al., 2011; O'Connor et al., 2016). Fire risk assessments depend on two critical inputs that require additional refinement: spatially explicit fuels data and an understanding of how fuels influence burn severity under varying weather conditions.

Vegetation structure and fuels vary substantially across heterogeneous landscapes (Keane et al., 2012), but most landscapes lack accurate canopy and surface fuels maps. The LANDFIRE program enhanced fire risk planning capabilities by providing national, wall-to-wall fuels maps for fire behavior models (Ryan & Opperman, 2013). However, LANDFIRE's utility is limited for fine-scale applications. Canopy fuels are predicted with low accuracy in many vegetation types (Keane et al., 2006; Moran et al., 2020; Reeves et al., 2009), and fuels data must be quality checked and calibrated prior to use (Stratton, 2009). Locally derived maps can improve predictions of fuel characteristics (Engelstad et al., 2019) and fire spread (Krasnow et al., 2009). In addition, surface fuels are mapped as categorical fuel models or fuel beds that are primarily suited for estimating fire behavior and effects and may not accurately predict actual fuel loads (Hyde et al., 2015; Keane et al., 2013). Incorporating local data to improve vegetation structure and surface fuels maps could support better estimation of wildlife habitat (Harmon et al., 1986); carbon storage, fire combustion, and smoke emissions (Weise & Wright, 2014); and optimal firefighter escape routes (Campbell et al., 2017) and safety zones (Dennison et al., 2014).

Anticipating fire behavior as climate change and fire activity accelerate is an increasingly pressing challenge in

fire-prone landscapes where vegetation may reburn more frequently than their historical baseline (Coop et al., 2020; Enright et al., 2015; Halofsky et al., 2020; Prichard et al., 2017). In many forests throughout western North America, burned areas can limit subsequent fire spread and severity due to reduced postfire fuel loads and continuity, but the duration of self-limitation varies by forest type, burn severity, fire season weather, and trajectories of postfire fuels development (McKenzie et al., 2011; Parks et al., 2014, 2015; Stevens-Rumann et al., 2016; see tab. 2 in Prichard et al., 2017). In US Northern Rocky Mountain subalpine forests where lodgepole pine (*Pinus contorta* var. *latifolia*) dominates postfire succession, self-regulation was previously thought to last >100 years for spread and even longer for severity due to slow development of fuels capable of supporting crown fire (Despain & Sellers, 1977; Romme, 1982). This assumption did not hold when fires in 1988 severely burned extensive areas of forests of all ages under extremely dry and windy conditions (Renkin & Despain, 1992; Romme & Despain, 1989). Recent studies suggest that initial burning may only limit subsequent fire spread for ~10–20 years in western US forests (Buma et al., 2020; Prichard et al., 2017), but effects on subsequent burn severity are less clear. Some studies conclude that areas of high-severity fire are more likely to reburn severely after only 10–12 years (Harvey et al., 2016), whereas others indicate that burn severity is self-regulated for decades (Parks et al., 2014; Stevens-Rumann et al., 2016) or more than a century (Bigler et al., 2005). In less than 25 years, lodgepole pine forests regenerating from stand-replacing fire can accumulate sufficient canopy and surface fuels to support crown fire (Nelson et al., 2016, 2017) and to reburn as stand-replacing fire (Turner et al., 2019). However, whether fuel loads and continuity in young subalpine forests support high-severity fire across extensive reburned areas and how strongly fuels limit burn severity in reburns are incompletely understood.

Spatial data on vegetation structure and fuels can be used to quantify relationships between fuels and burn severity in reburns. Fuels, weather, and topography interact to influence burn severity, and fuels tend to be a limiting factor in dry forests adapted to frequent, low-severity fire (Schoennagel et al., 2004). In moist subalpine forests that typically burn infrequently and at high severity, fuels are usually plentiful and extreme fire weather is the dominant driver of fire behavior (Bessie & Johnson, 1995; Turner et al., 1994; Turner & Romme, 1994). However, these relationships may shift if subalpine forests change from climate- to fuel-limited systems under increasingly frequent fire (Hessburg et al., 2019). Studies exploring the relationship between fuels and burn severity (e.g., Bessie & Johnson, 1995; Nelson et al., 2017; Parks et al., 2018; Stevens-Rumann et al., 2016) often rely on fuels data from sparse field plots, simulated fire behavior, or national maps.

A spatially continuous, accurate fuels map overcomes many of the limitations of other approaches, which include high sampling effort or sampling bias (field plots), deterministic relationships between fuels and severity (simulated fire behavior), and low accuracy of predicted fuels (national maps). In this study, we combined airborne light detection and ranging (lidar), aerial imagery, and field data to map fuels in forests and

shrublands across a large landscape centered on Grand Teton National Park (Wyoming, USA; Figure 1). Airborne lidar and imagery fusion can characterize three-dimensional vegetation structure and fuels at landscape scales with high spatial resolution (Lefsky et al., 2002; Lepczyk et al., 2021; Szpakowski & Jensen, 2019). We expected lidar–imagery fusion would best predict fuel metrics nearest to the top of the canopy (e.g., canopy

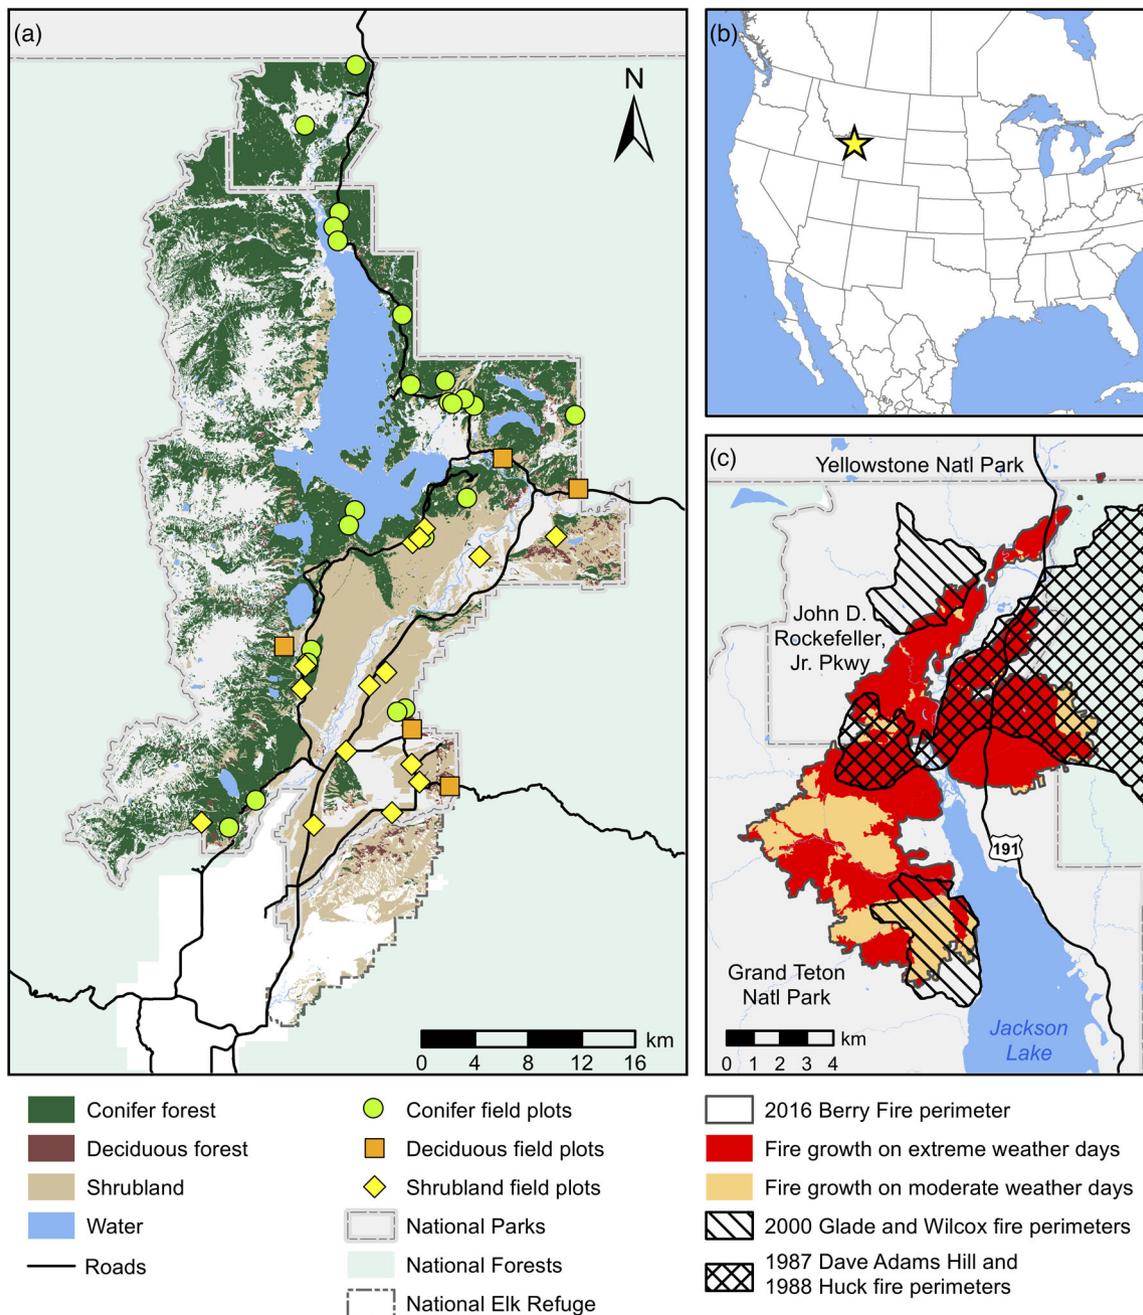

FIGURE 1 (a) Vegetation map and 2019 field plot locations within the footprint of the final fuels map, including Grand Teton National Park, John D. Rockefeller, Jr. Memorial Parkway, and the National Elk Refuge. (b) Location of study area (star) within North America. (c) 2016 Berry Fire footprint. Colors show areas within the footprint that burned under extreme (red) and moderate (orange) fire weather. Lines identify areas that returned 1987 or 1988 fire perimeters (crosshatched) or 2000 fire perimeters (parallel lines).

height and cover) and decrease in goodness-of-fit for within-canopy fuels (e.g., canopy base height; Andersen et al., 2005; Chamberlain et al., 2021; Erdody & Moskal, 2010; Jakubowski et al., 2013). In forests, we expected lowest predictive power for surface fuels, which included downed coarse woody debris (CWD) and shrubs, although CWD has been successfully derived from lidar in some forest types (Blanchard et al., 2011; Joyce et al., 2019; Pesonen et al., 2008; Tanhuanpää et al., 2015; van Aardt et al., 2011). We did not expect lidar to effectively differentiate between finer surface fuels (e.g., litter, duff, fine wood, and herbaceous fuels) under forest canopies, so these were not mapped.

We then used this map to ask two questions in a subalpine forest reburn: (1) How do prefire fuels and burn severity compare between young (~30-year-old) and mature (>125-year-old) forests that burned under similar fire weather conditions? We expected young forests to have similar or higher fuel loads and burn severity, as well as lower canopy base heights, relative to mature forests (Nelson et al., 2016; Turner et al., 2019). (2) How well do prefire fuels and forest structure predict burn severity under extreme versus moderate fire weather? We expected fuels and forest structure to be weak predictors of burn severity despite the presence of large areas of young forest within the fire perimeter, because young forests would not be fuel limited. However, we expected fuels would better predict burn severity under moderate versus extreme fire weather, because under extreme conditions the influence of weather would overwhelm that of fuels (Bessie & Johnson, 1995; Collins et al., 2019; Meigs et al., 2020).

METHODS

Study area

The study area encompasses ~1450 km² in northwest Wyoming in the US Northern Rocky Mountains and includes Grand Teton National Park, the John D. Rockefeller, Jr. Memorial Parkway, and the National Elk Refuge (hereafter collectively referred to as “GRTE”; Figure 1). Along with Yellowstone National Park and several national forests, GRTE anchors the Greater Yellowstone Ecosystem, a 89,000-km² area that is one of the largest protected temperate ecosystems on Earth (YNP, 2017). The GRTE is bounded on the west by the Teton Range, and elevations span 1900 m along the Jackson Hole Valley to 4200 m at the summit of Grand Teton (Cogan et al., 2005). Shrublands dominated by mountain big sagebrush (*Artemisia tridentata* ssp. *vaseyana*) characterize the lower-elevation, relatively flat valley floor

(Figure 1a). Montane and subalpine conifer forests cover most of the vegetated area of the park. Dominant forest types include low- to mid-elevation lodgepole pine forests and Douglas-fir (*Pseudotsuga menziesii* var. *glauca*) woodlands, higher-elevation subalpine fir (*Abies lasiocarpa*)–Engelmann spruce (*Picea engelmannii*) forests, and whitebark pine (*Pinus albicaulis*) forests near upper treeline (3000 m). Small pockets of deciduous forests dominated by quaking aspen (*Populus tremuloides*) are interspersed at intermediate elevations. Given complex and variable topographic conditions and disturbance histories throughout the landscape, forest types and tree species are often intermixed. At lower elevations, summers are warm and dry with a mean July temperature of 16.6°C and 554 mm of annual precipitation, most of which falls as snow (Moose, Wyoming, 1981–2010 climate normals; WRCC, 2020a). Temperatures cool and precipitation increases at higher elevations.

Throughout the US Northern Rocky Mountains, conifer forests and woodlands have historically burned infrequently at high or mixed severity, though lower-elevation forest types also burn at low severity at shorter fire intervals (Baker, 2009). For over 10,000 years, Indigenous peoples including the Eastern Shoshone, Shoshone-Bannock, Blackfeet, Crow (Apsáalooke), Salish Kootenai (Flathead), Aaniiih (Gros Ventre), and Niimiipu (Nez Perce) peoples occupied and used land in Greater Yellowstone before being forcibly removed during the creation of the National Parks (Native Land Digital, 2021; Spence, 1999). Indigenous burning is well documented throughout the western United States, but evidence suggests that climate remained the dominant driver of fire regimes in higher-elevation forests of the Northern Rocky Mountains except in localized areas such as settlements and travel routes (Baker, 2002; Whitlock et al., 2010). In subalpine, lodgepole pine-dominated forests, stand-replacing fires typically occurred every 100–300 years during periods of extreme drought and high winds (Bessie & Johnson, 1995; Higuera et al., 2011; Renkin & Despain, 1992; Romme & Despain, 1989; Whitlock et al., 2008). In Grand Teton National Park and the Jackson Hole Valley, extensive, stand-replacing fires occurred in the late 1800s, initiating synchronous, widespread postfire regeneration of lodgepole pine and aspen (Brandege, 1898; Loope & Gruell, 1973). Many of the older mixed conifer, Douglas-fir, and spruce-fir stands originated from stand-replacing fire in the 1600s–1700s (Sibold et al., 2014). Fires were suppressed during a portion of the 20th century, but past fire suppression was not always effective and had minimal effects on the stand-replacing fire regimes that characterize forest types in this region (Hansen et al., 2020; Schoennagel et al., 2004; Turner et al., 1994). Except for a few years following the 1988 fire season, wildfires have been allowed to burn for resource

benefits since 1972 in GRTE when they are not a threat to life or infrastructure (GRTE, 2009; Knight et al., 2014; Loope & Wood, 1976). Annual area burned over the past 50 years has been relatively low compared to the full extent of the study area, but there have been 11 years with >1000 ha burned, most of which have occurred since the year 2000.

The 2016 Berry Fire

The largest fire in recorded GRTE history, the Berry Fire was discovered on 25 July 2016 and burned 8143 ha over more than 2 months, mostly in subalpine, lodgepole pine-dominated forest (Figure 1c; MTBS Project, 2019). The lightning-ignited fire burned entirely within national park or national forest areas and was managed primarily for ecological objectives. The Berry Fire included 4 days (22 August, 23–24 August, and 11 September) of high fire spread under extreme fire weather characterized by dry conditions and high wind (6077 ha burned, 28% average relative humidity with maximum wind gusts between 43 and 82 km h⁻¹; GeoMAC, 2016; WRCC, 2020b). The remaining 2066 ha burned under more moderate fire weather (44% average relative humidity with maximum

wind gusts between 23 and 61 km h⁻¹). In addition to burning mature (>125-year-old; Brandegee, 1898; Sibold et al., 2014) forest, 43% of the Berry Fire reburned <30-year-old forest regenerating following the 1987 Dave Adams Hill Fire, 1988 Huck Fire, 2000 Glade Fire, and 2000 Wilcox Fire.

Predicting and mapping forest and shrubland structure and fuels

We adapted established best practices to map vegetation attributes from airborne lidar and imagery (Figure 2; Laes et al., 2011; Mitchell et al., 2012; White et al., 2013).

Data sources and initial processing

Airborne discrete-return, medium-resolution (0.7 m nominal pulse spacing and up to 4 returns pulse⁻¹, resulting in 5.7 points m⁻²), lidar data were collected using a Leica ALS70 sensor for GRTE during summer 2014 (Woolpert, 2015). Woolpert (2015) reviewed, classified, and processed lidar point clouds; vertical accuracy of bare earth points was 0.074 m root-mean-squared error

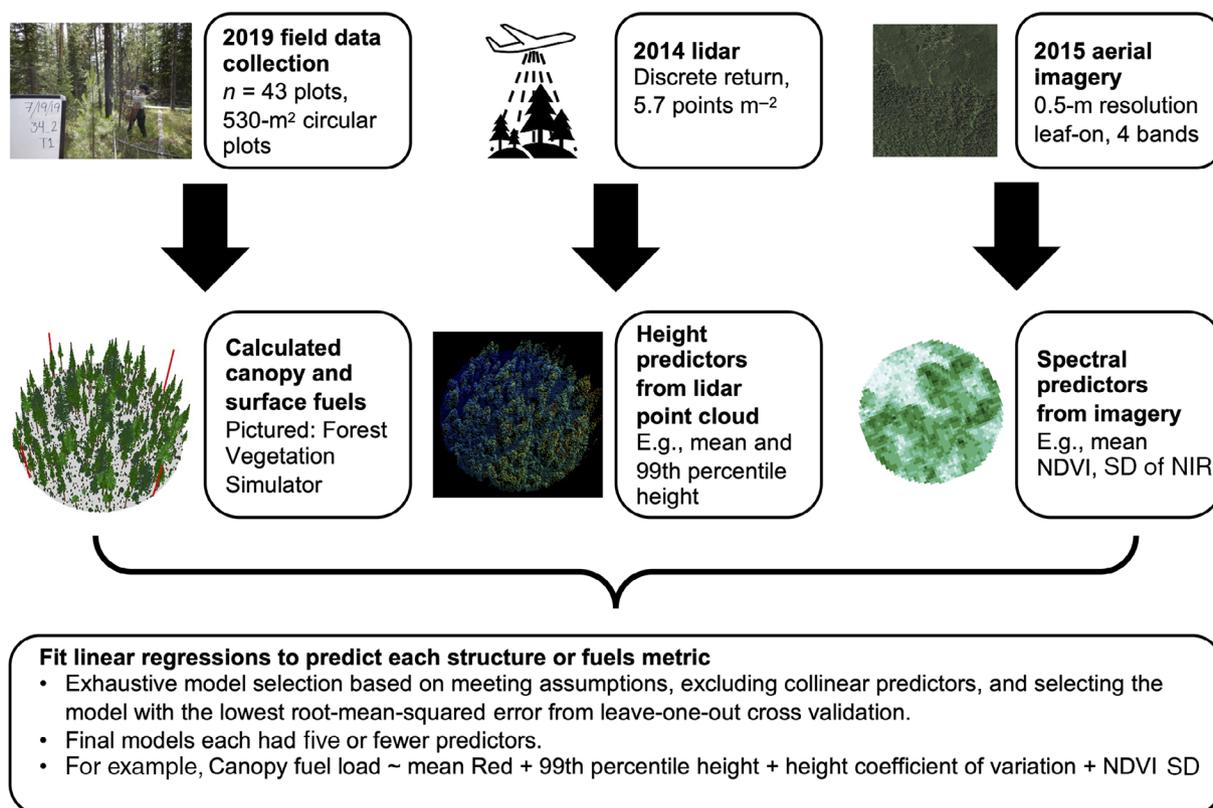

FIGURE 2 Flow chart outlining methods for using lidar-imagery fusion with field data collection to map canopy and surface fuel characteristics. NDVI, normalized difference vegetation index; NIR, near infrared; SD, standard deviation

(RMSE). We prepared point clouds for plot selection and analysis by removing points classified as noise, buildings, water, ignored ground, and overlap and reclassifying remaining nonground points as surface (0.1- to 2-m height) or canopy vegetation (2–60 m). Points >60-m height were excluded from further analysis based on the maximum height of dominant conifers (Braziunas et al., 2018; Burns & Honkala, 1990).

We acquired 2015 leaf-on aerial imagery for visible and near-infrared bands (0.5-m resolution) from the National Agriculture Imagery Program (NAIP; NAIP, 2015). We also obtained a 2005 vegetation map for the study region, which had an overall thematic accuracy of 82% (Cogan et al., 2005). We used three broad vegetation types to guide our study design and analysis: conifer forest, deciduous forest, and shrubland (Figure 1a).

Field data collection

Vegetation structure and fuels were sampled during summer 2019. We first excluded areas that were disturbed or managed after acquisition of remotely sensed data (GRTE, unpublished data; USDA Forest Service, 2019). We then used stratified random sampling to select plots based on vegetation type, lidar-derived 90th percentile canopy height, and lidar-derived canopy (forests) or shrub (shrublands) cover (see Appendix S1: Table S1). We additionally sampled two plots that represented target conditions: first, dense young forest regenerating from severe fire, and second, sparse postfire recovery with abundant downed wood. All plots were separated by >500 m except for two that were 290 m apart. In total, we sampled 43 circular 530-m² plots (23 conifer, 15 shrubland, and 5 deciduous; plot radius = 13 m) that covered a wide range of site, vegetation structure, and fuels conditions (Table 1, Figure 1a). We recorded plot center with a Trimble Geo 7X. Average postprocessed horizontal precision was 0.12 m, and average vertical precision was 0.16 m.

To quantify forest structure and canopy fuels in field plots, we measured the dbh, species, and status (live, dead, or dead with foliage) of every tree >1.4 m in height. Trees at plot edges were counted if >50% of their crown was within the plot. For all trees >7.6 cm dbh, we also recorded tree height and crown base height. We developed species-specific regression models to estimate height and crown base height of smaller trees <7.6 cm dbh. Due to the time lag between the lidar flight and field data collection, we assumed dead trees with foliage in 2019 were alive in 2015 and included them in structure and fuel metric calculations. For one plot in which tree density exceeded 35,000 stems ha⁻¹, individual trees were counted in only one-fourth of the plot area. Live saplings

between 0.1 and 1.4 m in height were tallied by species in a 2 × 26-m belt transect (total area = 52 m²). Average sapling height was estimated by measuring the height of one stem closest to each 5-m mark along the transect.

To quantify surface fuel characteristics, we established two perpendicular transects that intersected at plot center, with a 1-m buffer to avoid double-counting (total length = 50 m). We used Brown's planar intercepts (Brown, 1974) to measure CWD (1000-h fuels, >7.6 cm diameter) and line intercepts (Coulloudon et al., 1999) to measure sapling/shrub cover and height by species. We included trees <2-m height in shrub line intercepts because the surface fuel layer includes all vegetation up to 2 m in height (Keane, 2015). We estimated sapling/shrub percent dead in eight 0.5-m² quadrats spaced a minimum of 5 m apart along each transect (total area = 2 m²).

Derivation of fuel and structure metrics from field data

Forest structure, CWD cover and biomass, and sapling/shrub cover and height were derived following standard methods (Table 1, Figure 2; Brown, 1974; Coulloudon et al., 1999). We used Forest Vegetation Simulator (FVS; Dixon, 2002) Complete Package Software Version 2020.03.11 to quantify canopy fuel metrics, including canopy height and cover, based on the Tetons Variant (Keyser & Dixon, 2008). The FVS uses species-specific allometric equations for a given variant to estimate fuel loads within the canopy. Canopy fuels are defined and calculated in different ways. Following FVS, we defined canopy fuel load as standing live foliage biomass, canopy bulk density (CBD) as the maximum 13-ft (4-m) running mean within the canopy fuel profile, and canopy base height (CBH) as the lowest height at which CBD exceeds 0.011 kg m⁻³ (Rebain, 2010; Scott & Reinhardt, 2001).

Derivation of potential predictor variables from lidar and imagery

We clipped lidar and imagery to plot boundaries and derived a suite of potential predictor values based on their success in predicting fuels in previous studies (Appendix S1: Table S1; Figure 2; Erdody & Moskal, 2010). Lidar predictors included summary vegetation height statistics, canopy cover, and shrub cover. From NAIP imagery, we calculated 0.5-m resolution pseudo-normalized difference vegetation index (NDVI) from the red and near-infrared bands (Jensen, 2007) and texture homogeneity for all bands within a 7 × 7 moving window (Moskal & Franklin, 2002). Imagery predictors included summary statistics

TABLE 1 Topographic conditions, forest structure, and fuel metrics for plots sampled in 2019

Measurement	Description	Conifer forest (n = 23)	Deciduous forest (n = 5)	Shrubland (n = 15)
Topographic conditions				
Elevation (m)	Elevation at plot center	2091 (55) 1944–2217	2083 (30) 2052–2128	2045 (50) 1959–2155
Slope (°)	Dominant slope	5 (5) 0–16	9 (5) 3–14	4 (7) 0–26
Aspect (°)	Dominant aspect (excludes two plots that were flat)	200 (107) 6–356	170 (98) 92–302	215 (84) 76–314
Forest structure				
Tree density (stems ha ⁻¹)	Density of trees >1.4 m height	3573 (7269) 170–36,238	2972 (1694) 1149–5575	—
Tree basal area (m ² ha ⁻¹)	Basal area for trees >1.4 m height	23.1 (10.5) 0.8–37.5	21.6 (16.5) 8.1–47.5	—
Sapling density (stems ha ⁻¹)	Density of saplings between 0.1 and 1.4 m height	7926 (19,059) 0–93,846	3192 (2899) 0–7308	—
Sapling height (m)	Mean height of saplings between 0.1 and 1.4 m height. Excludes plots where no saplings present	0.7 (0.2) 0.4–1.0	0.9 (0.0) 0.9–1.0	—
Canopy fuel layer				
Canopy cover (CC, %)	Vertically projected cover of the suspended canopy onto the ground	41 (15) 5–63	66 (22) 40–93	—
Canopy height (CH, m)	Average height of the top of the vegetated canopy	18.5 (7.2) 4.3–34.1	12.9 (6.2) 9.1–23.8	—
Canopy fuel load (CFL, kg m ⁻²)	Amount of canopy fuel consumed in a crown fire. Quantified as standing live foliage biomass	1.00 (0.45) 0.03–1.85	—	—
Canopy bulk density (CBD, kg m ⁻³)	Amount of burnable canopy biomass in a given volume of space. Quantified as maximum 13-ft (4-m) running mean within the canopy fuel profile (Rebain, 2010; Scott & Reinhardt, 2001)	0.093 (0.045) 0.009–0.194	—	—
Canopy base height (CBH, m)	Lowest height at which CBD exceeds 0.011 kg m ⁻¹ (Rebain, 2010; Scott & Reinhardt, 2001)	0.6 (0.5) 0.3–2.4	—	—
Surface fuel layer				
Coarse woody debris (CWD) cover (%)	Cover of downed coarse woody debris (1000-h woody fuels, >7.6 cm diameter)	11 (7) 3–24	4 (3) 0–10	—
CWD biomass (Mg ha ⁻¹)	Quantified following Brown (1974), includes sound and rotten, adjusted for slope	62.4 (39.8) 7.7–151.2	20.6 (20.4) 0–54.8	—
Sapling/shrub cover (%)	Percent cover of surface fuel layer, which includes all shrubs >0.1-m height and trees <2-m height	22 (14) 5–51	24 (15) 3–46	42 (17) 16–77
Sapling/shrub height (m)	Average height of surface fuel layer. Average height is based on top height of individual shrubs and weighted by species percent cover	0.7 (0.3) 0.3–1.4	0.7 (0.1) 0.6–0.8	0.6 (0.2) 0.2–1.0
Sapling/shrub percent dead (%)	Average percent dead of surface fuel layer by volume	9 (9) 0–36	8 (3) 4–11	23 (12) 4–48
Sagebrush cover (%)	Percent cover of sagebrush species (<i>Artemisia</i> spp.)	—	—	27 (16) 0–54

Note: Values are expressed as mean, with SD in parentheses, and range.

and mean homogeneity for each band. This resulted in a total of 10 lidar-derived predictors and 30 imagery-derived predictors.

Predicting fuels and structure with lidar-imagery fusion

We developed linear regression models for each vegetation structure and fuel metric (Table 2; Appendix S1: Table S2; Figure 2). We used exhaustive best subsets model selection to fit models to either all forest plots (conifer and deciduous, $n = 28$), conifer plots only ($n = 23$), or shrubland plots only ($n = 15$). The number of predictors for each model was limited to a maximum of five (forest or conifer models) or three (shrubland models) to minimize overfitting. Models were first assessed to confirm that they met assumptions of linearity based on residual plots and normality based on quantile-quantile plots, and dependent variables were transformed as needed to meet assumptions (Appendix S1:

Table S2). Models with strongly correlated predictors (Pearson's $|r| > 0.7$), multicollinearity assessed as variance inflation factor > 5 , or high influence of individual observations (Cook's distance $D > 1$) were excluded from consideration. We selected final models based on the lowest root-mean-squared-error from leave-one-out cross-validation.

Mapping fuels and structure

We used final regression models to project fuels and vegetation structure throughout the study region at 30-m resolution. We did not map areas managed or disturbed following acquisition of remotely sensed data in 2014. Some mapped values were unrealistic or far outside the range of field observations. These outlier values were set to either the natural minimum or maximum (e.g., 0% or 100% canopy cover) or twice the maximum value observed in the field. We compared final lidar-imagery fusion canopy fuels maps, as well

TABLE 2 Performance of best models for predicting structure and fuels

Structure or fuels metric	Vegetation type(s) included in model	n	Adjusted R^2	R^2	RMSE	RMSEcv
Forest structure						
Tree density (stems ha^{-1})	Conifer, deciduous	28	0.72	0.77	0.45 (1419)	0.57

Note: Values in parentheses are back-transformed RMSE, if applicable. For metrics that were transformed to meet model assumptions (see Appendix S1: Table S2), root-mean-squared error is also calculated from back-transformed predicted values. Note that the sagebrush cover model was fit to the proportion of sagebrush cover relative to total sapling/shrub cover.

Abbreviations: RMSE, root-mean-squared error; RMSEcv, root-mean-squared error of leave-one-out cross-validation.

as LANDFIRE fuels maps, with our field data (see Appendix S2).

Q1: How do fuels and burn severity compare in young versus mature subalpine forest?

Within the Berry Fire perimeter (Figure 1c), we identified areas of mature forest that had not previously burned for over 125 years using perimeter data from Grand Teton National Park (unpublished data) and Monitoring Trends in Burn Severity (MTBS; Eidenshink et al., 2007; MTBS Project, 2019). We compared mature forest fuels and burn severity with young, ~30-year-old forest that burned as stand-replacing fire in 1987 or 1988. We restricted comparison to areas that burned under similar fire weather (i.e., high fire spread days only; GeoMAC, 2016), were classified as conifer forest prior to the Berry Fire (Cogan et al., 2005), and were within GRTE. We quantified burn severity using relative differenced normalized burn ratio (RdNBR; Miller & Thode, 2007; MTBS Project, 2019), which effectively characterizes field-measured burn severity in the region across a range of stand ages (Abendroth, 2008; Harvey, 2015; Saberi, 2019). We excluded RdNBR values that were likely unburned ($RdNBR < 0$) or anomalously high ($RdNBR > 2000$) and used a regionally calibrated threshold to delineate stand-replacing fire ($RdNBR > 675$; Harvey et al., 2016).

In both young and mature forest that burned in the Berry Fire, we randomly selected 30 points separated by >500 m to avoid spatial autocorrelation (Harvey et al., 2014, 2016). To strengthen inferences from these observational data, we used propensity score matching based on elevation and slope to exclude eight points, four each from young and mature forest, that fell outside overlapping ranges (Butsic et al., 2017). For remaining points (total $n = 52$), we obtained RdNBR from the closest 30-m resolution MTBS grid cell, and we used grid cell footprints to extract lidar and imagery predictors and calculate fuel loads (using equations from Appendix S1: Table S2). We compared forest structure, canopy and surface fuels, and burn severity between young and mature forests with two-sided Wilcoxon rank-sum tests.

Q2: How well do fuels predict burn severity under extreme versus moderate fire weather?

We assessed how well fuels and forest structure predicted burn severity within the full Berry Fire perimeter, including

all reburned areas (Figure 1c). We again used RdNBR (values between 0 and 2000) to quantify burn severity, excluded areas outside of GRTE, and only included areas classified as conifer forest or recently burned vegetation in the 2005 vegetation map. Areas were delineated as having burned under extreme fire weather (22 August, 23–24 August, and 11 September fire growth) or relatively moderate fire weather (all other days). For each fire weather condition, we randomly selected 50 points ($n = 100$ total) separated by >500 m and determined RdNBR and fuel loads as described above. We assigned approximate burn date based on fire progression maps (GeoMAC, 2016).

We fit separate linear mixed effects models to predict burn severity on either extreme or moderate weather days from forest structure and fuels as fixed effects and burn date as a random effect to account for daily variability in fire weather. We transformed fuels predictors to meet model assumptions (see Appendix S1: Table S2). For strongly correlated predictors (Pearson's $|r| > 0.7$), we retained the predictor hypothesized to directly affect burn severity or more strongly correlated with RdNBR. This resulted in basal area, canopy height, canopy cover, and CBD being excluded from model fitting. We then performed exhaustive model selection and selected the top models as those where all predictors were significant ($p < 0.05$) and Akaike information criterion corrected for small sample size (AIC_c) was within two of the best AIC_c model. We used residual and quantile–quantile plots to determine that models met assumptions, and model residuals were not spatially autocorrelated based on Moran's I . Model fit was assessed using variance explained by fixed effects (marginal $R^2_{LMM(m)}$) and by the full model (conditional $R^2_{LMM(c)}$; Nakagawa & Schielzeth, 2013).

All data processing, analysis, and map creation were performed using ArcGIS Desktop 10.6 (ESRI, Redlands, CA) and R Version 3.6.1 (R Core Team, 2019). We primarily relied on R packages `ape` (Paradis & Schliep, 2019), `asbio` (Aho, 2020), `car` (Fox & Weisberg, 2019), `caret` (Kuhn et al., 2019), `corrplot` (Wei & Simko, 2017), `doParallel` (Microsoft & Weston, 2019a), `fasterize` (Ross, 2018), `foreach` (Microsoft & Weston, 2019b), `glm` (Zvoleff, 2020), `leaps` (Lumley & Miller, 2017), `lidR` (Roussel & Auty, 2019), `lme4` (Bates et al., 2015), `lmerTest` (Kuznetsova et al., 2017), `MatchIt` (Ho et al., 2011), `MuMIn` (Barton, 2019), `openxlsx` (Schauberger & Walker, 2019), `optimx` (Nash & Varadhan, 2011), `qpcR` (Spiess, 2018), `raster` (Hijmans, 2019), `RColorBrewer` (Neuwirth, 2014), `rgdal` (Bivand et al., 2019), `rgeos` (Bivand & Rundel, 2019), `RSQLite` (Muller et al., 2019), `sf` (Pebesma, 2018), `sp` (Pebesma & Bivand, 2005), `tidyverse` (Wickham et al., 2019), and `tmap` (Tennekes, 2018).

RESULTS

Predicting and mapping forest and shrubland structure and fuels

Predicting fuels and structure with lidar-imagery fusion

Lidar and imagery variables strongly predicted forest and shrubland structure and fuel metrics (R^2 from 0.65 to 0.95; Table 2, Figure 3; Appendix S1: Figure S1). Leave-one-out cross-validation RMSEs were between 11% and 38% higher than RMSEs for models fit to the full data set. Top-of-canopy metrics canopy height ($R^2 = 0.95$) and cover ($R^2 = 0.78$) generally had higher goodness-of-fit than surface fuel metrics with the exception of conifer forest sapling/shrub cover, which had a higher R^2 (0.84) than canopy cover. Models for stand basal area ($R^2 = 0.86$) and within-canopy fuel metrics (R^2 from 0.87 to 0.90) performed nearly as well as canopy height. Sapling/shrub height in conifer forests ($R^2 = 0.65$) and sapling/shrub cover in shrubland ($R^2 = 0.66$) had the poorest model fits. We did not predict sapling density or height because models did not meet linear regression assumptions.

Most top models included both lidar- and imagery-derived predictors (Appendix S1: Table S2). A lidar-derived metric generally had the highest predictive power for canopy fuel metrics, whereas an imagery-derived metric had the highest predictive power for all surface fuel metrics except sapling/shrub cover in shrublands. Final models for canopy base height and sapling/shrub percent dead included only imagery predictors. No top models included only lidar predictors.

Mapping fuels and structure

Mapped fuel and structure distributions aligned well with field data (Figure 4a,b; Appendix S1: Figures S2–S4). Histograms of mapped and observed data peaked at similar values, although field observations were sometimes bimodal or multimodal. Mapped canopy base heights skewed slightly taller than field observations, although in both cases most CBHs were short (<1 m height). Some metrics were reclassified to minimum or maximum bounds; this affected 5.7% of mapped values in forests and 14.0% of mapped values in shrublands (Appendix S1: Table S3). Proportion sagebrush in shrublands was most often outside of bounds (44.8% of values). Other metrics that more frequently (>5% of mapped values) exceeded either minimum or

maximum thresholds before reclassification were CWD biomass, CWD cover, sapling/shrub cover, and sapling/shrub height in conifer forests.

Maps of forest and shrubland structure and fuels captured expected patterns across much of the study landscape (Figure 4c,d; Appendix S1: Figures S5–S8). For example, areas within 2006 and 2009 fire perimeters had low canopy fuel loads and patches of high CWD cover and biomass. Shrubland was dominated by sagebrush at low, but not high, elevations. However, some predictions appeared erratic in locations that were less represented by field data. For example, at higher elevations and on steeper slopes within the rugged terrain of the Tetons, canopy and surface fuels were consistently predicted to be higher than the landscape average.

Q1: How do fuels and burn severity compare in young versus mature subalpine forest?

Young and mature forests that burned in the Berry Fire had similar canopy fuel load (median 1.33 and 1.27 kg m⁻², respectively, $p = 0.59$), canopy base height (0.6 m, $p = 0.19$), basal area (25.5 and 24.5 m² ha⁻¹, $p = 0.33$), CWD biomass (29.5 and 37.5 Mg ha⁻¹, $p = 0.12$), and sapling/shrub height (0.3 and 0.6 m, $p = 0.21$; Figure 5; Appendix S1: Figure S9). However, compared to mature forests, young forests had higher CBD (median 0.163 vs. 0.098 kg m⁻³, $p < 0.001$), canopy cover (67% vs. 47%, $p = 0.001$), tree density (5029 vs. 1761 trees ha⁻¹, $p < 0.001$), and CWD cover (11% vs. 8%, $p = 0.01$), but lower canopy height (14.5 vs. 24.5 m, $p < 0.001$) and sapling/shrub cover (13% vs. 26%, $p < 0.001$). Thus, across a similar range of canopy fuel loads, canopy fuels were much more densely packed in young compared to mature forests (Figure 5).

Young and mature forest burned at similar burn severity (median RdNBR 667 and 758, respectively, $p = 0.29$; Figure 6) on days of similar, extreme fire weather. At least half of the sampled grid cells burned as stand-replacing fire in both young and mature forests (RdNBR > 675).

Q2: How well do fuels predict burn severity under extreme versus moderate fire weather?

On days of extreme fire weather, higher burn severity was best predicted by higher tree density and sapling/shrub

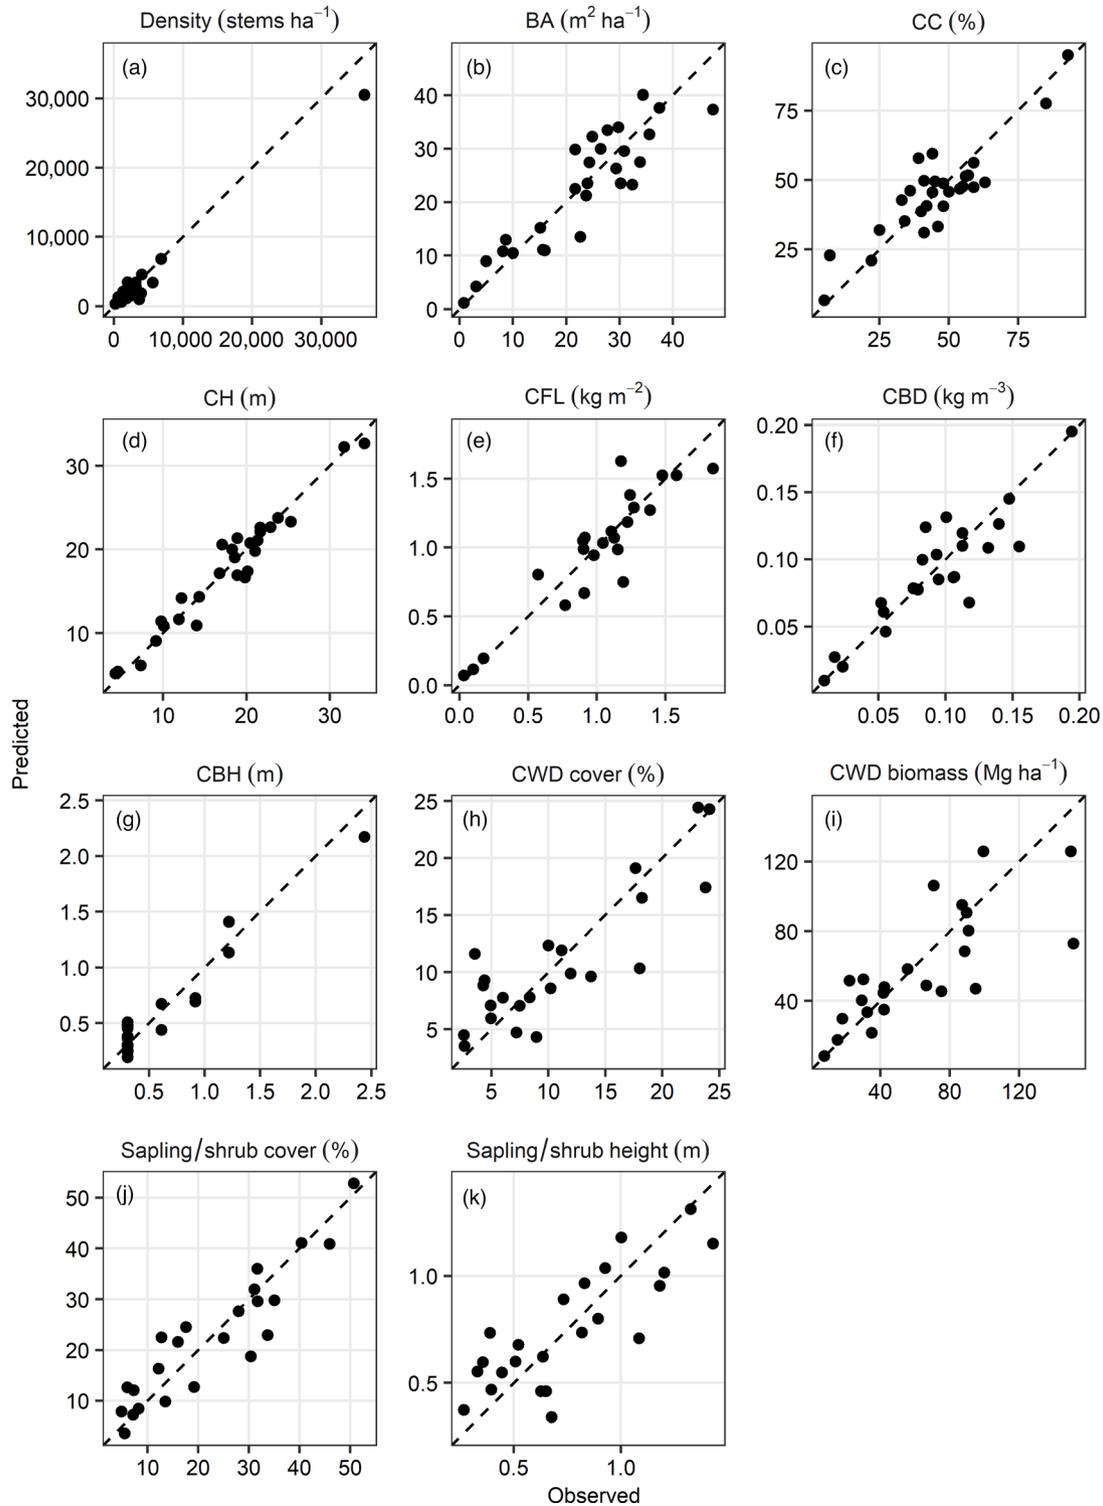

FIGURE 3 Predicted versus observed (field data) values for final forest structure and fuels regression models. Note that some models were fit to transformed values (see Appendix S1: Table S2). Dashed lines are 1:1 lines. (a–d) Models fit to combined conifer and deciduous plots ($n = 28$). (e–k) Models fit to conifer forest only ($n = 23$). BA, basal area; CBD, canopy bulk density; CBH, canopy base height; CC, canopy cover; CFL, canopy fuel load; CH, canopy height; CWD, coarse woody debris

cover, and burn date did not improve model fit (fixed effects marginal $R^2_{\text{LMM}(m)} = 0.27$ and full model conditional $R^2_{\text{LMM}(c)} = 0.27$; Table 3). On days of moderate fire

weather, higher burn severity was best predicted by higher coarse wood biomass, tree density, and sapling/shrub cover but with lower explanatory power ($R^2_{\text{LMM}(m)} = 0.15$ in top

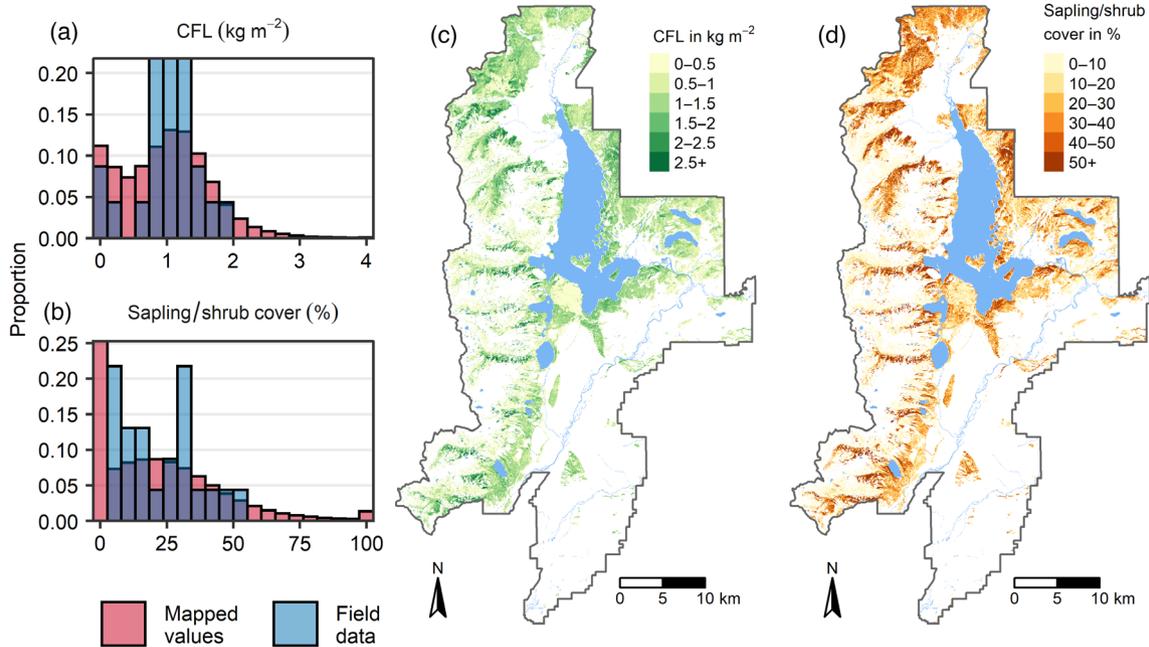

FIGURE 4 (a, b) Histograms showing distribution of mapped values ($n = 505,240$; blue) versus field data observations ($n = 23$, red) for canopy fuel load (CFL) and sapling/shrub cover in conifer forests. Overlapping areas are in purple. (c, d) Final lidar–imagery fusion fuels maps for canopy fuel load and sapling/shrub cover for conifer forests at 30-m resolution. Water is shown in blue.

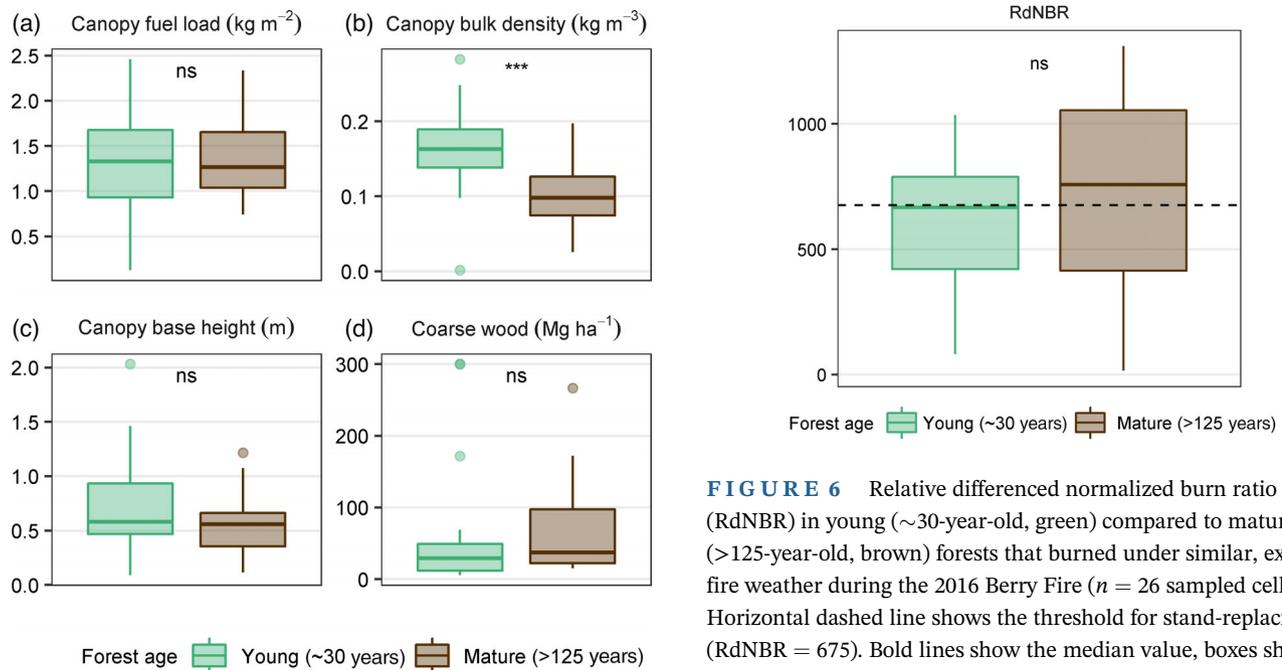

FIGURE 5 (a–c) Canopy and (d) surface fuels in young (~30-year-old, green) compared to mature (>125-year-old, brown) forests that burned during the 2016 Berry Fire ($n = 28$ sampled cells each). Bold lines show the median value, boxes show the interquartile range (IQR), and whiskers extend $1.5 \times$ IQR or to the most extreme data point. Results of Wilcoxon rank-sum tests indicate whether differences between distributions are not statistically significant (ns) or statistically significant at $p < 0.001$ (***).

FIGURE 6 Relative differenced normalized burn ratio (RdNBR) in young (~30-year-old, green) compared to mature (>125-year-old, brown) forests that burned under similar, extreme fire weather during the 2016 Berry Fire ($n = 26$ sampled cells each). Horizontal dashed line shows the threshold for stand-replacing fire (RdNBR = 675). Bold lines show the median value, boxes show the interquartile range (IQR), and whiskers extend $1.5 \times$ IQR or to the most extreme data point. Results of Wilcoxon rank-sum tests indicate that differences between distributions are not statistically significant (ns).

model); burn date explained more variability and improved model fit ($R^2_{\text{LMM}(c)} = 0.51$ in top model). A second moderate fire weather model included only tree density ($R^2_{\text{LMM}(m)} = 0.06$, $R^2_{\text{LMM}(c)} = 0.46$).

TABLE 3 Linear mixed effects models predicting burn severity on extreme versus moderate fire weather days, including all top models within two AIC_c in which all predictors were significant ($p < 0.05$)

Fire weather	AIC_c	$R^2_{LMM(m)}$	$R^2_{LMM(c)}$	Fixed effects	Estimate	t	p	Random effect
Extreme	743.9	0.27	0.27	Intercept	−1368.8	−2.482	0.02	Burn date
				Ln(Tree density)	256.4	3.519	<0.001	
				Sapling/shrub cover	7.6	3.345	0.002	
Moderate	727.6	0.15	0.51	Intercept	−915.5	−2.275	0.03	Burn date

				Sapling/shrub cover	4.4	2.038	0.05	
Moderate	728.9	0.06	0.46	Intercept	−307.4	−0.877	0.39	Burn date
				Ln(Tree density)	108.4	2.346	0.02	

Note: Variance explained is reported for fixed effects only (marginal $R^2_{LMM(m)}$) and for the full mixed effects model (conditional $R^2_{LMM(c)}$). Abbreviation: AIC_c , Akaike information criterion corrected for small sample size.

DISCUSSION

Fusion of lidar and aerial imagery predicted canopy and surface fuels in a large fire-prone landscape with high accuracy across a wide range of woody vegetation structures. Although canopy metrics were generally predicted with highest accuracy, surface fuels, including downed coarse wood, were predicted surprisingly well. Using this fuels map to assess burn severity in a changing fire regime revealed that young (~30-year-old) postfire forests had abundant, densely packed canopy fuels and burned at similar severity as mature forests under similar weather conditions. Fuels were weak predictors of burn severity in the Berry Fire, which included a large proportion of short-interval reburn, but contrary to our hypothesis, fuels better predicted severity under extreme rather than moderate fire weather. Our findings are relevant for subalpine landscapes in the US Northern Rocky Mountains that are increasingly dominated by young, postfire lodgepole pine forests vulnerable to short-interval fire.

Lidar-imagery fusion effectively predicted and mapped vegetation structure and fuels

Lidar-imagery fusion models performed well and led to maps that appropriately represented spatial patterns and variability in vegetation structure and fuels throughout much of the study region. Lidar availability is increasing across the United States (NOAA, 2021), and we demonstrated that medium-resolution lidar ($5.7 \text{ points m}^{-2}$) can effectively characterize canopy and surface fuel metrics that are critically important for fire and resource managers. Ideally, field data should be collected within 1 year of

acquisition of remotely sensed data (Laes et al., 2011). However, we show that models can perform well despite a 5-year gap between lidar and field data collection in forests and shrublands where vegetation changes slowly in the absence of disturbance. Most top models included both lidar and imagery predictors, indicating that lidar and imagery were complementary and enhanced model performance. This is consistent with previous studies that found lidar-imagery fusion was superior to using either lidar or imagery predictors alone (Erdody & Moskal, 2010; Jakubowski et al., 2013; Mutlu et al., 2008).

As expected, fuel and structure metrics closer to the top of the canopy were generally predicted with higher accuracy than surface fuels. However, within-canopy and surface fuel layer predictions performed better than anticipated. For example, CWD cover and biomass were strongly predicted despite being well below and often obscured by the top of the forest canopy, which is important because CWD is highly variable and difficult to assess across subalpine forested landscapes (Tinker & Knight, 2000). Strong model predictions may be due to consistent patterns of forest and fuel succession in this region following stand-replacing disturbances. Coarse woody debris is high 10–20 years after severe fire and declines as forests recover, achieve canopy closure, and increase in height, but subsequently increases after 100–200 years as trees die and fall, creating gaps in the canopy (Kashian et al., 2013; Lotan et al., 1985; Romme, 1982). Similarly, CBH starts low, increases, and then declines as gaps enable growth of trees in the understory. As indirect proxies, predictors that characterize successional changes in total and within-plot variability in biomass or leaf area (e.g., NDVI; Jensen, 2007) or in height may be well suited to predict these within-canopy or surface fuel metrics (Pesonen et al., 2008).

Young and mature subalpine forests had similar fuel loads and burn severity

Young forests did not limit burn severity in the Berry Fire. As hypothesized, fuel loads and burn severity were similar or higher in young compared to mature subalpine forests that burned under similar fire weather. Our findings are consistent with rapid serotinous lodgepole pine regeneration and fuels recovery after stand-replacing fire in mature forests (Nelson et al., 2016; Turner et al., 2004). We found that young forests had low canopy base heights and high canopy bulk densities, which enable crown fire under extreme fire weather conditions (Nelson et al., 2017; Van Wagner, 1977, 1989). Fires can limit subsequent burn severity for over 20 years in some western US forests (Parks et al., 2014; Stevens-Rumann et al., 2016), and our results suggest that burn severity is limited for less than 30 years in lodgepole pine-dominated subalpine forests. Given the combination of abundant, densely packed canopy fuels close to the ground and high CWD cover and biomass, we might have expected even higher burn severity in young versus mature forest. Reburns where nearly all prefire biomass was consumed, including foliage, young trees, and CWD, were observed in the field in the Berry Fire (Turner et al., 2019). However, these higher severities may be poorly differentiated by remotely sensed indices of burn severity, which characterize canopy mortality well but are less able to detect variation in dead biomass consumption or surface burn severity (Saber, 2019).

Understanding whether young forests will limit fire spread or severity is critical for anticipating fire behavior and forest recovery. Fire modelers update fuels maps based on expert knowledge of fire behavior and whether recent disturbances have altered fuels (Stratton, 2009). Our findings suggest that by 30 years postfire, subalpine lodgepole pine-dominated forests such as those prevalent throughout Greater Yellowstone can have similar fuel loads and even higher CBD compared to mature forests and should not be considered effective fire breaks, meaning they may neither slow fire spread nor reduce burn severity. This also has important implications for future forest landscapes, because severe short-interval fires can hamper subsequent forest recovery and initiate transitions to different forest types or nonforest vegetation (Coop et al., 2020; Enright et al., 2015; Prichard et al., 2017).

Forest structure and fuels predicted burn severity better on extreme weather days

Contrary to our hypothesis, forest structure and fuels better predicted burn severity under extreme versus moderate weather conditions. One possible explanation is that

burn severity is primarily detecting differences in canopy mortality due to crown fire. Under extreme fire weather, very low fuel moisture and high winds create the necessary conditions for crown fire initiation and spread (Renkin & Despain, 1992), but canopy fuel continuity may mediate fire effects. However, under moderate conditions with greater daily and potentially hourly variability in fire weather, the conditions for crown fire initiation and spread are less frequently met, and therefore, burn severity can be low even when fuels are abundant. It is nevertheless surprising that our results are contrary to the conventional wisdom that the relative importance of fuels is diminished under extreme fire weather in these forest types. It is important to note that we used daily fire progression maps, which are subject to error and uncertainty, as a proxy for moderate versus extreme fire weather. Fire risk assessments are often conducted based on worst-case weather scenarios, and our results indicate that prefire forest conditions can explain a small but meaningful amount of variation in potential fire effects on forests under extreme fire weather.

Surprisingly, canopy fuel metrics typically used to anticipate fire behavior (canopy fuel load, bulk density, and base height) were not included in top models. Instead, we found that tree density, sapling/shrub cover, and coarse wood biomass were the best predictors of burn severity. Although not strongly correlated in our study, higher tree densities were positively associated with higher canopy bulk densities and fuel loads, and horizontal continuity of canopy fuels increases with stand density. Sapling/shrub cover includes trees <2 m in height and thus quantifies ladder fuels, which enable surface fires to ignite the canopy, while high CWD biomass lengthens fire residence times and prolongs fuel consumption (Graham et al., 2004). Our analysis of the Berry Fire indicates significant but weak fuels effects on burn severity in a fire with a large proportion of reburned forest. Another recent study compared multiple fire hazard indices with burn severity in the Berry Fire and found that including canopy cover and surface fuel models mapped by LANDFIRE improved predictions of categorical burn severity, although relationships were still weak (Szapkowski et al., 2021). Our study supports the use of tree density, shrub cover, and coarse wood biomass as better predictors and provides new maps that can be incorporated into risk assessments. We further provide a benchmark that can be used to assess whether fuels more strongly regulate burn severity in future fires. It is important to note that our models did not include fine woody debris or herbaceous fuels, which we did not expect to be effectively characterized under a forest canopy by medium-resolution lidar. These fuels are often represented by categorical fuel models, but future studies should

explore methods for creating continuous fine surface fuels maps to further improve predicted fire behavior and effects.

Management applications for vegetation structure and fuels maps

Maps of vegetation structure and fuels can be used to support many management applications in combination with other geospatial data. For example, maps can be used in prefire planning to prioritize mechanical fuels treatment locations (North et al., 2015), to predict suppression difficulty under varying fire weather conditions (Rodríguez y Silva et al., 2014), or to identify and improve areas with relatively little vegetation to serve as fire-fighter safety zones (Dennison et al., 2014). Numerous studies have used lidar-derived data on vegetation structure to both understand and predict suitability of wildlife habitat (e.g., Garcia-Feced et al., 2011; Zhao et al., 2012). In Grand Teton National Park, resource managers and fire ecologists plan to test our map for quantifying the effectiveness of fuels treatments, monitoring fire effects, and mapping greater sage-grouse (*Centrocercus urophasianus*) habitat based on shrub height and sagebrush percent cover. If lidar is flown in future years, our regression models can be used to update the fuels map and assess landscape change.

Limitations and recommendations

The primary limitation of this study is that we were unable to perform an independent field-based validation of our fuels map. Therefore, we recommend that managers using either our fuels map or regression equations to predict fuels in other landscapes critically evaluate the reliability of mapped fuel metrics, ideally by using independent field observations to validate fuels predictions. In particular, values that were set to the minimum or maximum may not be representative of conditions on the ground. These values tend to occur at higher elevations and on steeper slopes and often coincide with forest edges (e.g., edge of forest and lake, edge of forest and road) and with higher proportions of nonvegetated surfaces (e.g., rocky or largely barren slopes). Variation in topographic conditions may affect the reliability of lidar predictor variables (Guo et al., 2010), whereas snow cover (present in some NAIP imagery at higher elevations) and shadows likely produce erroneous NAIP predictor values. Model precision (i.e., RMSE) should also be taken into consideration when using mapped values to plan management activities or make ecological interpretations.

Finally, we did not test how mechanical treatments or disturbance history might affect relationships between lidar and imagery predictors and fuel characteristics. Because the model for CBH only includes imagery predictors that do not penetrate the canopy, changes in CBH due to fuels treatments may not be well characterized by our models.

CONCLUSIONS

Quantifying forest fuels, and relationships between fuels and burn severity, is increasingly important for understanding how forest landscapes and fire behavior may change as fires recur more frequently. Here, we show that lidar–imagery fusion can accurately predict fuels across large landscapes, and fuels maps can improve understanding of how fuels affect burn severity. Although we found only weak evidence of fuels limiting burn severity in a single short (<30-year)-interval reburn, postfire fuel loads and forest recovery are likely to differ after short- compared to long-interval stand-replacing fire. As fire frequency increases, landscape-scale fuel loads and continuity in subalpine forests may decline to the point where they are no longer capable of sustaining large patches of high-severity fire (Braziunas et al., 2021; Hansen et al., 2020). Fire managers should continually reassess and update expectations about fire behavior in future forest landscapes. For now, however, our results suggest that young subalpine forests in the Northern Rocky Mountains have sufficient fuel loads to burn at high severity and should not be considered effective fire breaks.

AUTHOR CONTRIBUTIONS

Kristin H. Braziunas, Diane C. Abendroth, and Monica G. Turner designed the study; Kristin H. Braziunas led data collection and analysis with support from Diane C. Abendroth and Monica G. Turner; and Kristin H. Braziunas wrote the manuscript with contributions from Diane C. Abendroth and Monica G. Turner.

ACKNOWLEDGMENTS

We thank Windy Bunn, Chip Collins, Jacob Henrie, and Eric Neiswanger for their input during our initial project overview presentation at Grand Teton National Park headquarters. We are especially grateful to the many individuals who assisted with field data collection, including Paul Boehnlein, Olivia Burke, Claire Finucane, Nathan Kiel, Ray Lopez, Kate Patronik, Trond Simensen, Drew Smith, Ron Steffens, and Jill Stephenson. We also thank Todd Erdody, Anu Kramer, Chris Kucharik, Tyler Hoecker, Anthony Ives, Volker Radeloff, Adena Rissman,

Kyle Rodman, and two anonymous reviewers for providing constructive comments and/or technical assistance that greatly improved our study design and manuscript. We acknowledge funding from National Park Service Fuels Reserve Fund (National Park Service Task Agreement P17AC01466) and the University of Wisconsin Vilas Trust. Kristin H. Braziunas acknowledges support from a P.E.O. Ventura Neale Trust Endowed Scholar Award.

CONFLICT OF INTEREST
